Methods S1: Mortality and bang-bang theorem

We first show the influence of mortality on our model predictions as a robustness check, and second we show that the optimal control is of bang-bang type, with one unique switch, for annuals with constrained growth, fixed season length, and constant mortality.

How mortality affects our results

As a robustness check we extend the model with constant background mortality rate $m$. We assume that the vegetative part grows according to

$$\frac{dV}{dt} = u(t)F(V) \text{ with } V(0) = V_0,$$  \hspace{1cm} (S1.1)

and that the reproductive part grows according to

$$\frac{dR}{dt} = (1 - u(t)F(V))s(t),$$  \hspace{1cm} (S1.2)

where

$$s(t) = e^{-mt}$$  \hspace{1cm} (S1.3)

is the survival function and $m$ is the mortality rate. The reproductive mass depends on the survival, but the vegetative mass does not since we would otherwise account for the survival twice. According to Cohen (1976) the optimal control is a bang-bang control of reproduction. Below we provide an alternative proof of this fact, based on optimal control theory, showing also that there
will be one unique switch called the optimal flowering time \( t^*_F \) (Theorem 1). Therefore, the reproductive output is

\[
W(t^*_F) = \int_{t^*_F}^{T} F(V) s(t) dt = \frac{F(V(t^*_F))}{m} \left( e^{-mt^*_F} - e^{-mT} \right),
\]

where \( T \) the end of the season.

In Fig. S1 we show the optimal flowering time as a function of productivity for a few different mortality rates. We find in Fig. S1a that there is no internal maximum for the optimal flowering time, and in Fig. S1b,c that there is always an internal maximum for intermediate productivity, regardless of the mortality. This indicates that (low) mortality rates does not qualitatively change our results. Moreover, increasing the mortality always advances the optimal flowering time (higher mortality implies that it is better to reproduce earlier since then the risk of dying before reproduction decreases) and the effect of mortality decreases as productivity increases.

Figure S 1: Mortality decreases the survival, and affects the optimal flowering times as a function of productivity. Mortality is \( m = 0, 1, 2, 3 \), corresponding to no, low, intermediate and high mortality rate. The season length is \( E = 1 \) and the default mass values are \( V_{max} = 1 \) and \( V_0 = 0.02 \).

In the case of exponential growth, when mortality is included in the form of a survival function (Figure S1.a), we show how to find the optimal flowering time \( t^*_F \) analytically. In particular, in this case \( F(V) = PV \) and hence, using the bang-bang control in Theorem 1, the solution of (S1.1) becomes

\[
V(t) = V_0 e^{Pt}
\]

for \( 0 \leq t \leq t_F \), where \( t_F \) is the flowering time. To find \( t^*_F \) we maximize the reproductive output

\[
W(t_F) = \frac{PV_0}{m} e^{P t_F} \left( e^{-mt_F} - e^{-mT} \right)
\]
with respect to \( t_F \). Differentiating w.r.t. \( t_F \) and setting the derivative to zero yield

\[
\frac{dW(t_F)}{dt_F} = \frac{PV_0}{m} e^{pt_F} ((P - m)e^{-mt_F} - Pe^{-mT}) = 0.
\]

This implies that the optimal flowering time for exponential growth with mortality \( m \) is

\[
t^*_F = T - \frac{1}{m} \log \left( \frac{P}{P - m} \right).
\]

This is a maximum when the second derivative w.r.t. \( t_F \) of the reproductive output is negative, that is

\[
\frac{d^2 W(t_F)}{dt^2_F} = \frac{PV_0}{m} \left( e^{-mt_F} (P - m)^2 - P^2 e^{-mT} \right) e^{-pt_F} < 0,
\]

which holds true for \( t_F = t^*_F \).

This proves that, in the case of exponential growth, increasing the mortality always advances the optimal flowering time \( t^*_F \), and the effect of mortality decreases as productivity increases.

**Proof of optimal flowering bang-bang control with constrained growth and constant mortality**

The dynamic model for vegetative mass \( V = V(t) \) is given by

\[
\frac{dV}{dt}(t) = u(t)F(V(t)), \quad 0 < t < T, \quad V(0) = V_0 > 0
\]

where \( T \) is the end of the season, \( F(V) \) is the growth function and \( u(t) \in A \) is the control, in which

\[
a = \{ u(t) : [0, T] \to [0, 1] \text{ and } u(t) \text{ is measurable} \}
\]

denotes the set of admissible controls. We will prove results on properties on controls \( u(t) \) maximizing the reproductive output

\[
W = \int_0^T (1 - u(t))s(t)F(V(t))dt.
\]

In particular, we prove the following theorem.
Theorem 1. Suppose that the growth function $F(V)$ is positive, that $\frac{dF}{dV}(V)$ is a non-increasing function of $V$, and that the survival function is given by $s(t) = e^{-mt}$, where $m \geq 0$ is a constant mortality. Let $f(m, T) = \frac{m}{1-e^{-mT}}$ with $f(0, T) = \frac{1}{T}$. Assume that $u^*(t)$ is an optimal control maximizing the reproductive output in (S1.5). If $\frac{dF}{dV}(V_0) > f(m, T)$, then there exists an optimal flowering time $t^*_f \in (0, T)$ and $u^*(t)$ is given by the bang-bang control

$$u^*(t) = \begin{cases} 1 & \text{if } 0 \leq t \leq t^*_f \\ 0 & \text{if } t^*_f < t \leq T. \end{cases}$$

If $\frac{dF}{dV}(V_0) \leq f(m, T)$, then the optimal control is $u^*(t) = 0$ for all $t \in [0, T]$, that is, the optimal strategy is to flower immediately.

Proof. We intend to apply the Pontryagin maximum principle. Since the survival function $s(t)$ depends on time we first extend the dynamic model for vegetative mass (S1.4) by regarding time $t$ as an additional variable $\hat{t}(t) = t$ satisfying the differential equation $\frac{d}{dt}(\hat{t}) = 1$ for $0 \leq t \leq T$. Next, we define, for any $x_1, x_2, p_1, p_2 \in \mathbb{R}, a \in [0, 1]$, the Hamiltonian

$$H(x_1, x_2, p_1, p_2, a) = \left(\begin{array}{c} aF(x_1) \\ 1 \end{array}\right) \cdot \left(\begin{array}{c} p_1 \\ p_2 \end{array}\right) + (1 - a)s(x_2)F(x_1)$$

$$= F(x_1)s(x_2) + p_2 + aF(x_1)(p_1 - s(x_2)).$$

Assume that $u^*(t)$ is the optimal control for (S1.4), (S1.5) and let $V^*(t)$ be the corresponding trajectory for vegetative mass. Then the Pontryagin maximum principle, see e.g. Theorem 4.3 in Evans (1983), implies the existence of costates $p^*_1(t), p^*_2(t) : [0, T] \rightarrow \mathbb{R}$, satisfying the adjoint equations with $x_1 = V$ and $x_2 = t$

$$\frac{dp^*_1}{dt} = -\frac{dH}{dV} = -\frac{dF}{dV}(V^*(t))s(t) - u^*(t)\frac{dF}{dV}(V^*(t))(p^*_1(t) - s(t)), \quad (S1.6)$$

$$\frac{dp^*_2}{dt} = -\frac{dH}{dt} = m(1 - u^*(t))s(t)F(V^*(t))$$

with terminal conditions

$$p^*_1(T) = 0, \quad p^*_2(T) = 0.$$ 

The second adjoint equation, related to $\frac{d}{dt}(\hat{t}) = 1$, will not be used below. Using the maximum principle we get

$$H(V^*(t), t, p^*_1(t), p^*_2(t), u^*(t))$$

$$= \max_{a \in [0, 1]} \{ F(V^*(t))s(t) + p^*_2(t) + aF(V^*(t))(p^*_1(t) - s(t)) \}.$$

Since $p^*_1(T) = 0$ and $s(T) > 0$ we deduce, using continuity of solutions of (S1.6), that $p^*_1(t) < s(t)$ for $t \leq T$ close enough to $T$. Define $t_0$ as the smallest number in $[0, T]$ such that $p^*_1(t) < s(t)$ holds for all $t_0 < t \leq T$. Using $F(V) > 0$ and
that \( u^*(t) \) maximizes \( H \) we see that as long as \( t_0 < t \leq T \) we have \( u^*(t) = 0 \). Therefore, the costate equation (S1.6) simplifies to

\[
\frac{dp_1^*}{dt}(t) = -\frac{dF}{dV}(V^*(t))s(t), \quad \text{for} \quad t_0 < t \leq T. \tag{S1.7}
\]

We assume in the rest of the proof that \( m > 0 \), however, the case \( m = 0 \) follows by similar calculations. Integrating (S1.7) from \( t_0 \) to \( T \) yields

\[
p_1^*(t_0) = \int_{t_0}^{T} \frac{dF}{dV}(V^*(t))s(t)dt = \frac{dF}{dV}(V^*(t_0)) \int_{t_0}^{T} e^{-mt}dt \tag{S1.8}
\]

If \( t_0 = 0 \), then we must have \( p_1^*(0) \leq s(0) = 1 \) and so, by (S1.8),

\[
\frac{dF}{dV}(V_0) \leq \frac{m}{1 - e^{-mT}}. \tag{S1.9}
\]

If \( t_0 > 0 \), then \( p_1^*(t_0) = s(t_0) = e^{-mt_0} \) and (S1.8) implies

\[
\frac{dF}{dV}(V^*(t_0)) = \frac{m}{1 - e^{-mt_0 - mT}}. \tag{S1.10}
\]

By assumption \( \frac{dF}{dV} \) is a non-increasing function of \( V \) and \( F(V) \) is positive. Therefore, from (S1.4) it follows that \( V_0 \leq V^*(t_0) \) and thus \( \frac{dF}{dV}(V_0) \geq \frac{dF}{dV}(V^*(t_0)) \). Moreover, since \( t_0 > 0 \) we have \( \frac{m}{1 - e^{-mt_0 - mT}} > \frac{m}{1 - e^{-mT}} \) and hence

\[
\frac{dF}{dV}(V_0) > \frac{m}{1 - e^{-mT}}. \tag{S1.11}
\]

We can conclude that (S1.9) holds if and only if \( t_0 = 0 \), and (S1.11) holds if and only if \( t_0 > 0 \). Setting \( t_F^* = t_0 \), this proves the result on when it is optimal to flower immediately.

It remains to show that the optimal control is of bang-bang type and that there exists only one switch. In particular, we will show that the optimal control is given by

\[
u^*(t) = \begin{cases} 
1 & \text{if } 0 \leq t \leq t_0 \\
0 & \text{if } t_0 < t \leq T.
\end{cases} \tag{S1.12}
\]

To do so we first observe that if \( t_0 = 0 \) then \( u^*(t) = 0 \) for all \( t \in (0, T] \) and, therefore, we are done.

Assume that \( t_0 > 0 \). If we can show that \( p_1^*(t) > s(t) \) for all \( t \in [0, t_0) \), then \( u^*(t) = 1 \) for all \( t \in [0, t_0) \) and, therefore, we are done. From (S1.10) and since \( 0 < e^{m(t_0 - T)} < 1 \), we find the inequality

\[
\frac{dF}{dV}(V^*(t_0)) > m. \tag{S1.13}
\]

5
We also know that \( \frac{dF}{dV} \) is a non-increasing function of \( V \), and since \( F(V) \) is positive it follows from (S1.4) that \( V \) is a non-decreasing function of \( t \). Therefore, (S1.13) yields
\[
\frac{dF}{dV}(V^*(t)) > m \tag{S1.14}
\]
for all \( t \in [0, t_0] \). Since \( u^*(t) = 0 \) if \( p_1^*(t) < s(t) = e^{-mt} \), and \( u^*(t) = 1 \) if \( p_1^*(t) > s(t) = e^{-mt} \), we see that \( u^*(t)(p_1^*(t)e^{mt} - 1) \geq 0 \) for all \( t \in [0, T] \). Hence, (S1.14) yields
\[
\frac{dF}{dV}(V^*(t)) \left[ 1 + u^*(t)(p_1^*(t)e^{mt} - 1) \right] > m
\]
for all \( t \in [0, t_0] \). We obtain, according to (S1.6)
\[
-\frac{dp_1^*}{dt^*}(t) = \frac{dF}{dV}(V^*(t)) \left[ e^{-mt} + u^*(t)(p_1^*(t) - e^{-mt}) \right] > me^{-mt} = -\frac{ds}{dt}(t)
\]
which is equivalent to
\[
\frac{dp_1^*}{dt^*}(t) < \frac{ds}{dt}(t)
\]
for all \( t \in [0, t_0] \). Recalling that \( p_1^*(t_0) = s(t_0) \), the above inequality shows that (S1.12) is true. This proves the theorem for \( t^*_F = t_0 \). \( \square \)

**Methods S2: Analysing the optimal flowering time**

Here we go through the details in finding the optimal flowering time \( t^*_F \) that maximizes reproductive output \( W \), as well as a few criteria that needs to be fulfilled. There are three steps in the derivations:

1. Find a solution \( V(t) \) for the growth of the vegetative mass from the dynamics \( dV/dt = u(t)F(V) \) with \( V(0) = V_0 \). The solution is easily found for our growth types \( F(V) \).

2. Find the reproductive output. Using Theorem 1 we have the bang-bang reproduction
\[
u(t) = \begin{cases} 
1 & \text{if } 0 \leq t \leq t_F \\
0 & \text{if } t_F < t \leq T.
\end{cases}
\]

This means that the vegetative mass does not grow after the flowering time \( t_F \), and the reproductive mass does not grow before time \( t_F \). The reproductive output in this case is: \( W(t_F) = F(V(t_F)) \left[ V(T) - t_F \right] = F(V(t_F))(T - t_F) \), where \( T \) is the end of season.

3. Finally, in order to find the optimal flowering time \( t^*_F \) we solve \( dW/dt_F = 0 \). We also need to ascertain that \( d^2W/dt_F^2 < 0 \) so that the optimal flowering time is a maximum, exclude the possibility of more than one local maximum, and the possibility of a maximum on the boundary.
We are interested in three types of growth:

(a) Exponential growth: $F(V) = PV,$

(b) Logistic growth: $F(V) = PV(1 - V/V_{max}),$ and

(c) West-Brown-Enquist growth: $F(V) = PV^{3/4}(1 - (V/V_{max})^{1/4}).$

(a) Exponential growth
The plant grows according to

$$\frac{dV}{dt} = u(t)F(V) = u(t)PV, \tag{S2a.1}$$

where the allocation to vegetative growth is $u(t)$. Assuming the bang-bang control the differential equation has the solution

$$V(t) = V_0 e^{Pt},$$

for $0 \leq t \leq t_F$ where $V_0$ is the initial mass at time $t = 0$. The reproductive output, with the bang-bang control having flowering time $t_F$, is easy to find since $F(V(t_F))$ is constant after flowering,

$$W(t_F) = F(V(t_F)) \int_{t_F}^{T} dt = PV_0 e^{Pt_F}(T - t_F). \tag{S2a.2}$$

To find the optimal flowering time we differentiate this w.r.t. $t_F$ and set the derivative to zero,

$$\frac{dW}{dt_F} = -PV_0 e^{Pt_F} (P(t_F - T) + 1) = 0. \tag{S2a.3}$$

The solution is the optimal flowering time

$$t_F^* = T - \frac{1}{P}.$$ 

This is a maximum when the second derivative w.r.t. $t_F$ of the reproductive output,

$$\frac{d^2W}{dt_F^2} = -V_0 P^2 e^{Pt_F} (P(t_F - T) + 2), \tag{S2a.3}$$

is negative, which is the case when $t_F = t_F^* = T - \frac{1}{P}$. There is no productivity that maximizes $t_F$ since the derivative of $t_F^*$ w.r.t $P$ is always positive, meaning that the optimal flowering time always increases with increasing productivity,

$$\frac{dt_F^*}{dP} = \frac{d}{dP} \left( T - \frac{1}{P} \right) = \frac{1}{P^2} > 0. \tag{S2a.4}$$
(b) Logistic growth

The plant grows according to

$$\frac{dV}{dt} = u(t)PV \left(1 - \frac{V}{V_{max}}\right).$$

Assuming the bang-bang control the differential equation has the solution

$$V(t) = \frac{V_{max}V_0 e^{P_t}}{V_{max} + V_0 (e^{P_t} - 1)}, \quad (S2b.1)$$

for $0 \leq t \leq t_F$, where $V_{max}$ is the maximum vegetative mass. The reproductive output at the flowering time $t_F$ is

$$W(t_F) = F(V(t_F)) \int_{t_F}^{T} dt = PV(t_F) \left(1 - \frac{V(t_F)}{V_{max}}\right) (T - t_F), \quad (S2b.2)$$

and we find the optimal flowering time $t^*_F$ when $dW/dt_F = 0$. The derivative has the same sign as

$$f(t_F) = V_{max} - V_0 - V_{max} P T + PTV_0 + P(V_{max} - V_0)t_F + V_0 (1 + PT)e^{P_t_F} - PV_0 t_F e^{P_t_F} = 0,$$

assuming that $V_{max} > V_0$. This equation has a unique solution for $t_F$, which we will only find numerically. The solution is unique because

$$\frac{df(t_F)}{dT} = P(V_{max} - V_0) + (T - t_F)P^2 V_0 e^{P_t_F} > 0, \quad (S2b.3)$$

since $V_{max} > V_0$ and $T > t_F$. Therefore $f(t_F)$ is a monotonically increasing function and there can be only one or zero solutions to $f(t_F) = 0$. Assuming that $V_0$ is small, there exists a unique solution, which is the optimal flowering time $t^*_F$, since $W(t_F)$ grows initially at $t_F = 0$, and decreases at $t_F = T$.

Now we show that increasing the productivity can either delay or advance the optimal flowering time. By implicit derivation of $f(t_F)$ we find that the sign of $dt^*_F/dP$ is the same as the sign of

$$S = (T - t_F)(V_{max} - V_0) - (T + P t_F(T - t_F))V_0 e^{P_t_F}. \quad (S2b.4)$$

The first term is positive since $T > t_F$ and $V_{max} > V_0$. For low values of $P$ we get $dt^*_F/dP > 0$ (delayed optimal flowering) since the second negative term is small, but for large values of $P$ we get $dt^*_F/dP < 0$ (advanced optimal flowering) since the second negative term is dominating.
(c) West-Brown-Enquist growth

The plant grows according to (West et al., 2001)

\[
\frac{dV}{dt} = u(t)PV^{3/4} \left( 1 - \left( \frac{V}{V_{\text{max}}} \right)^{1/4} \right).
\]

Assuming the bang-bang control the differential equation has the solution

\[
V(t) = V_{\text{max}} \left( 1 - \left[ 1 - \left( \frac{V_0}{V_{\text{max}}} \right)^{1/4} \right] \exp \left( \frac{-Pt}{4V_{\text{max}}^{1/4}} \right) \right)^4,
\]

for \(0 \leq t \leq t_F\). The reproductive output is

\[
W(t_F) = PV(t_F)^{3/4} \left( 1 - \left( \frac{V(t_F)}{V_{\text{max}}} \right)^{1/4} \right) (T - t_F),
\]

and we find the optimal flowering time when \(dW/dt_F = 0\). The derivative has the same sign as

\[
\frac{df(t_F)}{dt_F} = a + 4ab(T - t_F) - (1 + bT)e^{bt_F} + bt_F e^{bt_F} = 0,
\]

where

\[
a = \left[ 1 - \left( \frac{V_0}{V_{\text{max}}} \right)^{1/4} \right] \quad \text{and} \quad b = \frac{P}{4V_{\text{max}}^{1/4}}.
\]

This equation has a unique solution for the optimal flowering time \(t_F^*\), which we will only find numerically. The solution is unique because

\[
\frac{df(t_F)}{dt_F} = -4ab - (T - t_F)b^2 e^{bt_F} < 0,
\]

since \(V_{\text{max}} > V_0\) and \(T > t_F\). Therefore \(f(t_F)\) is a monotonically decreasing function and there can be only one or zero solutions to \(f(t_F) = 0\). Assuming that \(V_0\) is small, there exists a unique solution, which is the optimal flowering time \(t_F^*\), since \(W(t_F)\) grows initially at \(t_F = 0\), and decreases at \(t_F = T\).

Now we show that increasing the productivity can either delay or advance the optimal flowering time. By implicit derivation of \(f(t_F)\) we find that the sign of \(dt_F^*/dP\) is the same as the sign of

\[
S = 4a \frac{db}{dP}(T - t_F) - (T + bt_F(T - t_F)) \frac{db}{dP} e^{bt_F}.
\]

The first term is positive since \(T > t_F\), \(db/dP > 0\) and \(a > 0\). For low values of \(b\) we get \(dt_F^*/dP > 0\) (delayed optimal flowering) since the second negative term is small, but for large values of \(b\) we get \(dt_F^*/dP < 0\) (advanced optimal flowering) since the second negative term is dominating.
