affect the proliferative and invasive abilities of epithelial cancer cells. Tumour microenvironment comprises not only stromal cells, mainly cancer-associated fibroblasts, but also immune cells of both the innate and adaptive system (tumour-associated macrophages, neutrophils, natural killer cells, and T and B lymphocytes), and endothelial cells. This results in an intricate web of mutual communications regulated by an extensively remodelled extracellular matrix, where the tumour cells are centrally engaged.

In this regard, cholangiocarcinoma, in particular the intrahepatic variant, has become the focus of mounting interest in the last years, largely because of the lack of effective therapies despite its rising incidence and high mortality rates worldwide. On the other hand, recent studies in pancreatic cancer, which similarly to cholangiocarcinoma, is highly desmoplastic, have argued against a tumour-promoting function of the tumour microenvironment. In this review, we will discuss recent developments concerning the role of each cellular population and their multifaceted interplay with the malignant biliary epithelial counterpart. We ultimately hope to provide the working knowledge on how their manipulation may lead to a therapeutic gain in cholangiocarcinoma.

**KEYWORDS**
cancer associated fibroblasts, immunotherapy, extracellular matrix, immune cells, tumor associated macrophages, tumor reactive stroma

**1 | INTRODUCTION**

The development of a highly reactive microenvironment in conjunction with the growth of the tumour mass is a functional hallmark of many epithelial cancers with pronounced invasiveness and shortage of therapeutic options. The tumour microenvironment is a heterogeneous, ‘multi-tissue’ compartment, encompassing stromal cells, in particular activated fibroblasts (so-called cancer-associated fibroblasts), and endothelial cells, along with a crowd of innate and adaptive immune cells (tumour-associated macrophages, neutrophils, natural killer cells, and T and B lymphocytes), which act in concert to provide tumour cells with a plethora of pro-invasive cues. In addition, extracellular matrix (ECM) degradation and remodelling support and encourage the reciprocal interactions among the different cell populations, thereby contributing to a pleomorphic milieu proficent to tumour growth and invasion. The result is the generation of a complex network of intercellular crosstalk. In other words, within this ‘ecosystem’, the non-malignant stromal and immune cell elements represent the ‘soil’ where the ‘seed’, namely the malignant epithelial counterpart, is not only hosted, but also nourished, aiding its engraftment and overgrowth.

In cholangiocarcinoma (CCA), including both the intrahepatic and the perihilar anatomical subtypes, the extent of the tumour stroma is so prominent that it outweighs the tumoural component. Other epithelial malignancies of glandular origin, including breast, prostate, gastric and pancreatic adenocarcinomas, feature an abundant desmoplasia, but the effects can be different, depending on the specific disease context. Many studies highlighted the pro-tumourigenic role played by the tumour microenvironment, and the classic view supports the concept that targeting tumour stroma may offer a valuable strategy to halt tumour progression. In contrast with tumour cells, whose genetic heterogeneity makes response to conventional chemotherapy unpredictable, stromal and immune cells are not transformed, and thus, offer a therapeutic advantage, as they display a much more predictable response to therapy. From this point of view, anti-angiogenesis therapy,

**Key points**

- Cholangiocarcinomas, including the intrahepatic and perihilar anatomical subtypes, are characterized by a prominent stromal reaction.
- In cholangiocarcinoma, the tumour microenvironment is populated by a heterogeneous plethora of cells, including not only stromal cells (mainly cancer-associated fibroblasts), but also innate immune cells (tumour-associated macrophages, neutrophils), and adaptive immune cells (tumour-infiltrating lymphocytes).
- Deciphering the complex interactions between malignant cholangiocytes and cells hosted in the tumour microenvironment is key to uncover novel therapeutic interventions targeting single cell compartments of the tumour microenvironment, in support of tumour cell-specific targeted therapies.
- Targeting stromal and immune cells may be relevant strategies to halt cholangiocarcinoma progression.
pioneered as an approach in some settings such as metastatic colorectal cancer, has shown to be effective. However, recent data derived from experimental models argue against the pro-invasive functions of the stromal reaction. In mouse models of pancreatic ductal adenocarcinoma, indeed, depletion of cancer-associated fibroblasts induced a more aggressive tumour phenotype and accelerated tumour spread with reduced survival, thus indicating that some stromal elements may act to restrain rather than stimulate tumour growth. Alternatively, homeostatic restoration of the desmoplastic stroma by reprogramming fibroblasts into their quiescent state is an effective strategy to slow progression of pancreatic cancer. The aim of this review is to clarify the role of the tumour microenvironment in CCA, and to understand if it can provide targets for therapeutic intervention. Therefore, we will examine the role of each cell compartment and its intricate interplay with the tumoural cells, at instances by highlighting results from other desmoplastic epithelial cancers, before discussing if their manipulation may lead indeed to a therapeutic gain.

2 | THE ROLE OF CANCER-ASSOCIATED FIBROBLASTS IN CCA

A major cellular population of the desmoplastic stroma of CCA is represented by fibroblast-like cells, called cancer-associated fibroblasts (CAFs). These cells are activated myofibroblasts, expressing α-smooth muscle actin (α-SMA) (Figure 1A). Most observations indicate that CAFs play a key role in mediating CCA growth and progression, as well as resistance to therapy. Hence, high α-SMA expression in the tumour stroma correlates with poor survival in patients with CCA. Important evidence of their role was provided by the demonstration that triggering CAF apoptosis with the BH3 mimetic navitoclax reduces tumour burden and metastasis in vivo in a syngeneic rat model of cholangiocarcinoma.15

2.1 | Mechanisms underlying CAF recruitment

CAFs constitute a phenotypically heterogeneous group of myofibroblasts, whose origin is still uncertain and probably multiple. For instance, distinct subpopulations of CAFs expressing specific cell surface markers such as podoplanin, a mucin-like transmembrane glycoprotein or CD10, a cell surface metalloprotease, have been associated with lymphatic spread or with different anatomical location respectively. Immunohistochemistry studies using cell type-specific markers have reported that these cells most likely originate from hepatic stellate cells (HSCs) and/or portal fibroblasts. Other potential cellular sources of CAFs include bone marrow-derived mesenchymal cells, which are recruited from the peripheral blood. On the other hand, the contribution of epithelial-to-mesenchymal transition (EMT) of cholangiocytes to myofibroblasts has been refuted in murine models of liver fibrosis using lineage-tracing

![Figure 1](https://example.com/figure1.png)

**FIGURE 1** Spatial relationships of different cell types in the tumour microenvironment of cholangiocarcinoma (CCA). Immunohistochemistry for α-smooth muscle actin (α-SMA) (A), CD45 (B), CD34 (C), and dual immunohistochemistry for α-SMA (brown) and podoplanin (blue) (D) of formalin-fixed paraffin-embedded tissue sections obtained from surgical specimens of a patient with intrahepatic CCA undergoing liver resection. (A) Cancer-associated fibroblasts identified by their immunoreactivity for α-SMA form a tight shell around the malignant bile ducts. (B) Innate inflammatory cells expressing CD45 (neutrophils, macrophages, NK cells) are located in close vicinity to a large vascular space (*) consistent with their recruitment into the tumour microenvironment from the circulating compartment. (C) Blood endothelial cells positive for CD34 are rarely observed nearby the neoplastic bile ducts, compared with (D) the numerous podoplanin+ lymphatic endothelial cells laying strictly adjacent to α-SMA+ cancer-associated fibroblasts in between the tumoural ducts. (A-C) counterstained with DAPI. Original magnification: 200×
techniques.  

Furthermore, in vivo xenotransplant studies with CCA cells demonstrated that CAFs are not generated through an EMT process of CCA cells, but rather their recruitment was regulated via platelet-derived growth factor (PDGF)-D secretion by CCA cells. PDGF-D promotes fibroblast migration through its cognate receptor PDGFRβ, and activation of its downstream effectors, Rho GTPase and c-Jun N-terminal kinase (JNK).  

In a murine model of breast cancer, also a highly desmoplastic tumour type, DNA damage in tumour cells during tumour initiation induces activation of fibroblasts via COX-2/prostaglandin E2 and activin-A. This pathway has not been explored in CCA.

### 2.2 Cross-talk between CAF and tumour cells

In the past years, the characterization of biliary epithelial cells and stromal cells from human surgical CCA resected specimens has provided new information on their crossstalk with CCA tumour cells and other immune cell types in the tumour stroma. CAFs are pivotal in this context as they are able to communicate in a multi-directional manner with virtually every cell type in the tumour microenvironment. The molecular regulation of this communication is rather challenging to dissect because of its high level of complexity, plasticity and dynamics. CAFs are able to enhance the malignant phenotype of CCA cells via various soluble factors, for example hepatocyte growth factor (HGF), transforming growth factor (TGF)-β, connective tissue growth factor (CTGF), epidermal growth factor (EGF), stromal cell-derived factor-1 (SDF-1) and angiogenesis factor (Vegf-C), which induce the chemotaxis of lymphatic endothelial cells to gather in a proper vascular bed also favouring CCA cell invasation (Figure 1C-D). Furthermore, in a syngeneic rat model of CCA, depletion of CAFs by navitoclax reduces the lymphatic vascularization of the tumour mass and more importantly, lymph node metastases in vivo.  

Accordingly, transcriptomic analysis of the tumour stroma in CCA found that a stromal signature enriched for TGF-β and TNF receptor superfamilies, associated with a strong expression of pro-inflammatory mediators, significantly correlated with poor prognosis. Taken together, these findings point towards an important tumour-supporting role of CAFs already at very early time points during tumour evolution.

### 2.3 Cross-talk between CAF and innate immune cells

Beside cancer cells, CAFs communicate extensively with cells of the immune system, including tumour-associated macrophages (TAMs). Monocytes and macrophages are of critical importance for the activation of fibroblasts, as originally noted by Ross studying skin wound healing. In murine models of liver fibrosis, hepatic macrophages promote disease progression via nuclear factor k-light-chain-enhancer of activated B cells (NF-kB)-dependent enhancement of HSC survival. In turn, CAFs have been shown to recruit macrophages in various murine and human tumours, thereby stimulating angiogenesis and tumour progression. While these results and the significant (molecular and cell biological) overlap between wound healing, fibrosis and tumour formation argue for a significant role of the CAF-macrophage axis in CCA, functional studies addressing this intriguing topic are missing. Besides cells of innate immunity, a large body of evidence supports a pivotal role of CAFs in the regulation of adaptive immunity in the tumour microenvironment. The vast array of cytokines, chemokines and proangiogenic factors secreted by CAFs, is believed to predominantly generate an immunosuppressive microenvironment. Compared with myofibroblasts, CAFs also express high levels of fibroblast activation protein (FAP), a membrane-bound serine protease implicated in ECM remodelling, and FAP overexpression has been reported in tumour stroma of highly invasive epithelial cancers, as pancreatic ductal adenocarcinoma. Interestingly, FAP expression identifies a subset of CAFs with up-regulated expression of pro-inflammatory genes, which promotes immunosuppression by recruiting myeloid-derived stromal cells (MDCs) in the tumour microenvironment via STAT3-CCL2 signalling. The immune-suppressive function of CAFs was convincingly demonstrated by immunogenic tumour (and stromal cell) necrosis in response to genetic
ablation of a CAF-subset in murine pancreatic adenocarcinoma.\textsuperscript{40} Of note, two independent groups reported a rather unexpected tumour progression upon CAFs depletion in murine tumour models, demonstrating that the consequences of CAF depletion are highly context-dependent.\textsuperscript{7,8} With respect to CCA, a small study analysing immune-related transcripts in resected biliary tract cancers (BTCs) displayed a significant association between the expression of cytotoxic T-lymphocyte antigen (CTLA)-4 and relapse-free survival.\textsuperscript{41} While these results are interesting and suggest an immunosuppressive environment promoting tumour progression, the functional relevance and molecular mechanisms of the cross-talk between CAFs and adaptive immune cells remains largely elusive in CCA. This topic will conceivably become of growing interest in the era of immunotherapy of solid tumours.

2.4 | Effects of CAF on ECM

Alongside the multitude of soluble factors enabling communications with the different cell types that populate the tumour microenvironment, CAFs produce major ECM components, such as tenasin-C and periostin, and secrete several MMPs. Coupled with those released by the cancer cells themselves, MMPs are essential to degrade and remodel the ECM, as pre-requisite for tumour progression. In CCA, CAFs express MMP1, MMP2, MMP3 and MMP9 and this phenotype is associated with tumours that are more aggressive.\textsuperscript{42,43} However, recent data indicate that in desmoplastic tumour microenvironments, CAFs can make passageways in the ECM in an MMP-independent manner. The basement membrane is the barrier that at the stage of carcinoma in situ, segregates tumour cells from the stroma, and it must be broken to let tumour cell spread through the surrounding tissues. In addition to proteolysis, rupturing of the basement membrane can be favoured by fine CAF movements dependent upon their overdeveloped contractility. By pulling and stretching the basement membrane, CAFs exert mechanical forces which soften the barrier integrity and lead to the formation of gaps permissive for cancer cell migration and invasion, as elegantly shown in an ex vivo model of colorectal cancer.\textsuperscript{44}

Some major ECM constituents, such as tenasin-C, osteopontin, and periostin, are newly synthetized in CCA, where they promote key tumour properties, as invasive cell growth, chemoresistance and metastatic spread.\textsuperscript{45,46} Moreover, their overexpression, mainly at the invasive front as in the case of tenasin-C, correlates with an increase in tumour size, lymph node metastatization and a worsen outcome.\textsuperscript{46} Periostin, in particular, has drawn increasing interest as a potential prognostic biomarker and putative molecular target in intrahepatic CCA (iCCA).\textsuperscript{45} Periostin is a glycoprotein belonging to the TGF-β family-inducible matricellular proteins, extensively represented also in the ECM of other desmoplastic epithelial cancers, as reported in pancreatic ductal adenocarcinoma.\textsuperscript{47} In desmoplastic tumours, CAFs are the main cell source of periostin. In malignant cholangiocytes, periostin interacts with other ECM components, particularly collagen type I and tenasin-C, and with integrins, particularly α5β1, α5β3, α5β5 and α6β4, leading to activation of a proliferative cascade mediated by phosphoinositide 3-kinase (PI3K)/AKT signalling.\textsuperscript{48} Of note, CCA cells express the periostin receptor, the α5 subunit of integrin, and knockdown of α5 integrin decreased tumour proliferation and invasion.\textsuperscript{49} Gene expression profiling of laser-capture microdissected stroma obtained from human iCCA revealed two additional ECM components, laminin and osteopontin, that besides being markedly up-regulated compared with non-tumour tissue, had also strong clinical relevance as they significantly correlated with poor prognosis.\textsuperscript{50} In particular, stromal overexpression of osteopontin and TGF-β2 were the most significant independent predictors in terms of both overall and disease-free survival.\textsuperscript{50} The ‘desmoplastic’ ECM can play a pro-tumorigenic effect, also thanks to its increased rigidity. External mechanical forces induce cells to change the tension and the structure of the cytoskeleton, exerting potent tumour suppressor functions in normal epithelia. Two intracellular mechanosensors, Yes-associated protein (YAP) and transcriptional coactivator with PDZ-binding motif (TAZ), are particularly sensitive to ECM stiffening and act as fundamental supervisors of both tissue repair mechanisms and tumour initiation and progression by regulating crucial cell functions, including proliferation, survival, plasticity and invasion.\textsuperscript{51} Once activated in tumour epithelial cells by nuclear translocation and interaction with the transcription factor TEAD, YAP/TAZ elicit a number of pro-invasive pathways, such as the mTOR/cyclin D1-mediated hyper-proliferation, the AKT-mediated escape from apoptosis, and the activation of the EMT program endowing tumoural cells with mesenchymal properties.\textsuperscript{52} Recent data show that alternative to association with TEAD, YAP/TAZ nuclear activity is inhibited by its association with the switching defective/sucrose non-fermenting (SWI/SNF) chromatin-remodelling complex through ARID1A,\textsuperscript{53} whose genetic inactivation has been reported in about 7% of iCCA.\textsuperscript{54} The association between ARID1A–SWI/SNF and YAP/TAZ is finely regulated by cellular mechanotransduction: whereas soft ECM favours YAP/TAZ inhibitory sequestration within the ARID1A-containing SWI/SNF, conversely stiff ECM induces YAP/TAZ detachment from SWI/SNF and their binding to TEAD.\textsuperscript{53} Notably, a stiff ECM enhances the activity of YAP/TAZ not only in cancer cells but also in stromal cells, including CAFs. Active nuclear
YAP was expressed by CAFs, and YAP depletion in CAFs reduced their tumour-promoting functions. In breast cancer, ECM stiffening regulates a feed-forward self-reinforcing loop that helps to maintain the CAFs phenotype by sustaining YAP activation. In turn, YAP controls the expression of cytoskeletal regulators, including ANLN and DIAPH3, and of the myosin light chain 9 (MYL9) that regulates CAFs contractility and motility.55

4 | THE ROLE OF THE INNATE IMMUNE SYSTEM IN CCA

Several innate immune cells encompassing macrophages, neutrophils and natural killer (NK) cells are present in the tumour microenvironment and they significantly affect cholangiocarcinogenesis (Figure 1B). Tumour-associated macrophages (TAMs) are the most relevant infiltrating immune cell population within the tumour microenvironment.56 High tissue macrophage density has been associated with poor prognosis of patients with CCA.57 Furthermore, circulating CD14+/CD16+ monocyte levels correlate with TAM infiltration and are associated with poor prognosis.58 CCA cells induce macrophage polarization towards the alternatively activated macrophage or M2 phenotype via the STAT3 pathway, these being associated with bad prognosis in patients with CCA.59 Macrophages, through their crosstalk with CCA cells participate in tumour growth by releasing a variety of inflammatory, growth and proliferative factors.60-62

Elevated preoperative peripheral blood neutrophil-to-lymphocyte (NLR) ratio is also a poor prognostic factor for intrahepatic and extrahepatic CCA,63-66 as well as in patients with advanced CCA undergoing chemotherapy.67,68 Distribution of tumour-associated neutrophils (TAN) in CCA tissue sections by immunohistochemical analysis of CD15, a marker of mature granulocytes, has revealed that patients with high CD15 expression have shorter disease-free survival time and overall survival than those with low expression.49 Moreover, neutrophil gelatinase-associated lipocalin (NGAL) expression in bile has been identified as a valuable candidate to discern malignant from benign biliary strictures.70

NK cells are innate lymphocytes with the capacity to recognize and eliminate tumour cells via the release of cytotoxic granules.71 This recognition is regulated by a plethora of activating and inhibitory immune receptors expressed on the surface of NK cells. With these, NK cells can sense and respond to ‘stressed’ cells, such as cancer cells, in the nearby area.71 The liver is enriched in NK cells compared with other lymphocytes and they represent up to 30%-40% of all liver lymphocytes.72 Despite this, little is known regarding NK cells in CCA. Instead, more studies have been performed in HCC where several immune receptors expressed by NK cells, such as CD96 and NKp30, have been associated with better prognosis.73,74 Furthermore, immunotherapy with infusion of activated allogeneic NK cells has also been performed in HCC patients with promising outcomes.75,76 However, before such treatments can be employed in CCA, it is necessary to determine if NK cells have the capacity to infiltrate CCA, which NK cell receptor-ligand interactions are important for recognition of CCA, and how NK cells are affected by evasion strategies employed by the tumour and its microenvironment.

4.1 | Mechanisms underlying innate immune cell recruitment

The mechanisms underpinning the complex innate immune response in CCA are still largely unknown. As mentioned above, macrophage polarization towards the tumour-promoting M2 state is associated with poor prognosis and metastasis in CCA.77 TAMs are a subtype of M2 macrophages with particular powerful tumour-promoting functions78 and derive mainly from CD14+/CD16+ circulating monocytes rather than from resident macrophages; indeed, the massive expansion of intrahepatic macrophages observed during chronic liver injury follows the influx of circulating monocytes.79 Monocyte recruitment into the liver is promoted by chemoattractant molecules, including monocyte chemoattractant protein-1 (MCP-1/CCL2), colony-stimulating factor (CSF)-1 and VEGF-A.80 Notably, intrahepatic macrophages are an important source of CCL2 that stimulates the migration of bone marrow-derived monocytes.81 Further, macrophage recruitment is supported by epithelial tumour cells and CAFs, and is also stimulated by regulatory pathways (Notch, IL6/STAT3, PI3K) and specific cytokines (IL1β), IL10, IL13 and IL4).82 In CCA, a stem cell-like compartment is particularly active in promoting recruitment of circulating monocytes along with their differentiation into TAMs, by releasing IL13, IL34 and osteoactivin. Importantly, TAMs associated with the cancer stem cell niche display unique features, including expression of both M1 and M2 phenotypic traits, increased adhesive and invasive capabilities, in vitro, and enhanced tumour-promoting activities, in vivo.83 This has lent support to the notion that different TAM subsets are present within the tumour, reflecting different hints derived from various cell niches. Finally, TAMs themselves modulate the CCA microenvironment by secreting TNF-α, TGF-β1, IL6, IL10 and VEGF-A,81 which support EMT, tumour growth and metastasis.

Infiltration of TANs has also been associated with poor prognosis in CCA.86 Recruitment of neutrophils in CCA is predominantly driven by CXCL5, which has direct chemoattractant effects on TANs in vitro through PI3K-AKT and ERK1/2 signalling pathways.84 TANs expressing CCL2 and CCL17 recruit TAMs and regulatory T lymphocytes, eventually generating an immunosuppressive environment, which sustains tumour promotion.

As aforementioned, CAFs are highly active in recruiting innate immune cells, and can play a dual role with both tumour-suppressive and tumour-promoting potential that may be partly explained by the regulatory state(s) and heterogeneity of CAFs. Beside recruiting immunosuppressive MDSCs and TAMs,39 CAFs attract and educate dendritic cells (DCs) into a regulatory state, attenuating the expression of antigen-presenting HLA molecules, reducing the capability to attract and activate tumour-infiltrating lymphocytes,85 and enhancing the ability of MDSCs to inhibit T-cell proliferation via FAP/STAT3/CCL2 axis.39
4.2 | Mechanisms whereby innate immune system influences tumour growth

Well in line with the above outlined heterogeneity and complexity of innate immune cells in tumour microenvironment, the mechanisms by which these cells impinge on tumour progression are diverse. TAMs are able to accelerate tumour progression on multiple levels. They take part in tumour angiogenesis via the secretion of pro-angiogenic (eg VEGF-A, angiopoietin, IL8) and pro-inflammatory mediators, such as cyclooxygenase (COX)-2 and inducible nitric oxide synthase (iNOS), supporting tumour growth beyond the limits of oxygen and nutrient diffusion. Additionally, macrophage-derived Wnt ligands, such as Wnt3a and Wnt7b, activate canonical Wnt pathway, contributing to CCA cell proliferation. Furthermore, TAMs are able to dampen the efficacy of anti-proliferative drugs against solid tumours in a substantial manner. Certain chemotherapeutic agents, for example doxorubicin, enhance TAM accumulation in the tumour microenvironment, ultimately attenuating their cytotoxic effects. Although the molecular underpinnings are still enigmatic, recent work by Lyssiotis’ group showed that in murine models of pancreatic ductal adenocarcinoma, pyrimidine species released by TAMs inhibit gemcitabine via functional interference with drug uptake and metabolism. This suggests that TAM metabolism is intertwined with that of cancer cells with the potential to modulate the therapeutic response of solid tumours. Anti-tumour immunity is another paramount effect played by TAMs. TAMs can suppress tumour-inhibiting T cells via different mechanisms, for example via depletion of essential metabolic precursors such as L-arginine by hypoxia-mediated up-regulation of arginase and iNOS. Within the macrophage population, the TIE2-expressing monocytes/macrophages (TEMs) represent a myeloid cell subset found in blood as well as in tumour tissue with relevance for tumour progression. TIE-2 is the receptor for angiopoietins, and TEMs are indeed highly pro-angiogenic. Furthermore, TEMs, via IL10, suppress T-cell proliferation, increase the CD4/CD8 ratio, and support the expansion of CD4^+CD25^highFOXP3^+ regulatory T lymphocytes (Tregs), highlighting TEMs as a vigorous immunosuppressive force in the tumour microenvironment. However, in CCA TEM abundance is associated with improved prognosis, suggesting additional, hitherto unknown mechanisms by which TEMs inhibit tumour progression.

In the innate immune system, NK cells are of pivotal importance given their ability to control microbial infections and tumour progression. Phenotypically, NK cells are defined as CD3^−CD56^ bright lymphocytes in humans and as CD3^−NK1.1^ lymphocytes in mice. Lysis of target cells, including neoplastic cells, is the hallmark function of NK cells and of paramount importance for their tumour-inhibiting efficacy. Anti-tumour effects of NK cells can be overcome by various means, for example conservation of MHC class I (MHC-I) expression, shedding of ligands for the activating NK receptor (eg NKG2DLs), and secretion of immunomodulatory molecules (eg TGF-β, prostaglandin E2, adenosine) by tumour cells, ultimately resulting in tumour progression. Interestingly, under defined conditions, NK cells can express programmed cell death protein-1 (PD-1) and CTLA-4, which are instrumental for anti-tumour T-cell responses and represent targets for several approved immunotherapy agents. The functional relevance of NK cells for CCA is only beginning to emerge. In vitro, activated NK cells have been shown to enhance the cytotoxic efficacy of cetuximab against human CCA cell lines, while in vivo, infusion of ex vivo-expanded human NK cells in HuCCT-1 xenografts in nude mice displayed significant tumour-inhibiting effects.

5 | THE ROLE OF ADAPTIVE IMMUNE SYSTEM IN CCA

Convincing evidence in both mouse models and human patients support the ability of the adaptive immune system to identify and target arising tumour cells, and thus, to behave as a primary defence against cancer. Tumour-infiltrating lymphocytes (TILs) are present in many solid tumours and form highly heterogeneous populations. While TILs can act against tumour cells to inhibit carcinogenesis and to hamper cancer progression (‘immune surveillance’), cancer cells devise stratagems to circumvent anti-cancer immune reactions and boost tumour progression (‘immune escape’). Tumour infiltrates include B lymphocytes, CD8^+ cytotoxic T lymphocytes, cytokine-secreting CD4^+ T helper lymphocytes, and Forkhead box P3 (FoxP3)^+ Tregs. Additionally, DCs as an important bridge between adaptive and innate immune responses are abundant in the tumour microenvironment and shuffle antigen towards the draining lymph node for immune activation.

In CCA, CD8^+ T lymphocytes have been studied in terms of presence and location within the tumour. Overall, CD4^+ TILs prevail in the peritumoural region, while CD8^+ TILs are mostly prevalent in the intratumoural tissue. More than half of resected CCAs are positive for CD8^+ TILs, of which 30% are reported positive for Granzyme B, indicating an activated and cytotoxic phenotype. Multiple studies confirm that enhanced CD4^+ and CD8^+ infiltrates (also in combination with low numbers of macrophages) in CCA and extrahepatic BTCs are associated with better overall survival, fewer lymph node metastases and reduced venous and perineural invasion, whereas low numbers of CD8^+ TILs are associated with poor overall survival. In addition, MHC-I expression in intrahepatic and extrahepatic CCA strongly correlates with the CD4^+ and CD8^+ tumour infiltrate and is associated with longer overall survival. Consistent with these findings, in BTCs, the total count of lymphocytes of the adaptive immune response showed a stepwise decrease in invasive and metastatic tumours compared with non-invasive precursors, suggesting a gradually developing immune escape of the tumour. The number of CD4^+ and CD8^+ lymphocytes in CCA tissue may additionally be influenced by DCs. It has been demonstrated that immature CD1a^+ DCs reside only in the tumour core, while mature CD83^+ DCs are found predominantly at the invasive front.
Moreover, the number of DCs at the invasive margin correlated with the number of CD4+ and CD8+ TILs in the tumour bulk. Additionally, mature DCs surrounded by CD4+ and CD8+ cells are observed at the cancer periphery, highlighting the importance of immune cell interactions in CCA. A similar finding was reported in colorectal carcinoma, indicating that these clusters of DCs and T lymphocytes are formed to maximize T-cell activation against the tumour.110,113 Takagi suggested a direct link between the abundance of mature DCs able to prime anti-tumour T cells at the invasive margin and the risk of cancer invasion and metastasis.110 Indeed, they could show that CD4+ and CD8+ T-cell infiltration in the cancerous tissue is enhanced by mature CD83+ DCs at the tumour-host interface of CCA, with CD83+ patients displaying a better prognosis and lower incidence of lymph node metastases than CD83- patients.110 Furthermore, patients classified with an advanced tumour stage showed significantly lower numbers of either immature or mature DCs.

While several studies have drawn attention to T cells, the role of B lymphocytes in CCA is still far from clear. B cells have been identified in TIL populations in BTC, but they are only rarely observed in patient tissues.105,106 Although high densities of CD20+ cells have been observed in low-grade tumours and associate with a favourable overall survival,106 future studies are needed to clarify their relevance.

6 | MECHANISMS OF IMMUNE SURVEILLANCE AND IMMUNE ESCAPE

The presence of immunogenic tumour-associated antigens has been demonstrated in CCA patients.114 Importantly, the cytotoxic reaction is balanced by immunosuppressive signals. Indeed, CCL2 secreted by tumour cells, TAMs, and CAFs, stimulates tumour-infiltrating T cells to acquire CD4/CD25 expression and become Tregs.115 Tumour-associated Tregs secrete IL10 and TGF-β, which inhibit cytotoxic T cells and NK cells and shape an immunosuppressive milieu. Further, Tregs bind IL2, making it unavailable in the tumour microenvironment and thus preventing the activation of additional immune cells.116 A recent study confirmed that CCA cells also activate natural Treg-like CD4+CD25+ cells, leading to an increased expression of TGF-β, which suppresses the immune response.117 TGF-β is overexpressed in CCA, and correlates with poor prognosis, lymph node and distant metastases, and tumour recurrence.118 However, TGF-β signalling also conveys a tumour-suppressing influence by inhibiting tumour growth in the early stage of malignant transformation.119

FoxP3 is a distinctive feature of Tregs but it is overexpressed also by tumour cells.120 Knockdown of FoxP3 in tumour cells in vitro reduced proliferation and invasiveness in CCA cells, inhibited T cell survival, and reduced IL10 and TGF-β signalling in the tumour microenvironment.120 Consequently, FoxP3 overexpression correlates with lymphatic metastasis, poor survival and shorter disease-free survival.111,120 Furthermore, FoxP3 overexpression is accompanied by CTLA-4 overexpression.140 Indeed, CTLA-4 is expressed on the surface of Tregs and has to bind to CD80 on antigen-presenting cells to exert inhibitory effects on cytotoxic cells.112 Interestingly, a deregulation of genes related to immune modulation in BTCs was more pronounced in the peritumoural than in the tumour tissue and facilitated tumour recurrence and chemo-resistance. Strong CD80 expression, likely reflecting the enrichment of activated Tregs in the microenvironment, correlated with resistance to adjuvant chemotherapy. Furthermore, the expression of CTLA4 in the peritumoural area has prognostic value highlighting the concept that immune escape in CCA associates with poor prognosis.31

In order to evade immune surveillance as mechanism of resistance, cancer cells frequently manipulate immune checkpoints such as PD-1 and CTLA-4, that once activated by their specific ligands (PD-L1 and CD152 respectively), promote peripheral T cell exhaustion. High expression of PD-L1 among other immune checkpoints and of tumour-specific neoantigens characterized a subset of CCA patients (5.9%, 14/239) with high mutational load and poor prognosis.121 Both PD-1 and PD-L1 are up-regulated in neoplastic cells,122-124 and overexpression is associated with increased invasiveness, poor outcome, and worse disease- and metastasis-free survival, especially when accompanied by low CD3+ or CD8+ infiltrate.109,122,125,126 Conversely, low PD-L1 expression (in combination with high MHC-I expression) was found to be related to favourable prognosis.127 Consequently, the PD-L1/PD-1 pathway might be responsible, to some extent, for lymphocyte apoptosis in CCA progression and account for an increased cancer’s malignant potential.

Notch signalling, an important morphogen in the liver, and a signalling mechanism associated with iCCA,128,129 can also modulate the immune cell regulation necessary for activation of T helper 1 cells130 and CD4+FoxP3+ Tregs.131 In addition, Notch may contribute to M1 polarization of macrophages and to their relationships with CAFs. Since Notch is also involved in T cell induction and in stimulating T cell effector secretory functions (IL10, IL22 and IFN-γ), it is tempting to hypothesize that Notch is crucial for directing T cell infiltrates in CCA.130,131

7 | THE INTERACTION BETWEEN THE IMMUNE SYSTEM AND THE NEOPLASTIC EPITHELIAL CELLS: LESSON FROM THE LYMPHOEPITHELIOMA-LIKE CCA

The lymphoepithelioma-like CCA (LEL-CCA) is a variant of iCCA with distinct epidemiological, morphological and clinical features. So far, 40 cases have been described, the majority in women from South-East Asia. In spite of this rarity, LEL-CCA is of interest because it represents a peculiar model of interaction between the immune and neoplastic compartment, and is characterized by significantly superior overall survival when compared with classical iCCA of corresponding stage.132-134 Histologically, LEL-CCA consists of undifferentiated epithelial cells and dense polyclonal lymphocyte infiltrate but in absence of a typical stromal reaction. Tumour cells are arranged in sheets and express the pankeratin A1/A3 and the biliary type cytokeratin K7 and K19135; markers of stemness such as CD133 and EpCAM are frequently expressed. The lymphoid
infiltrate includes CD3+ and, to a lesser extent, CD20+ cells, and interestingly, metastatic lesions of LEL-CCA lose the lymphoid component. Epstein-Barr virus (EBV) non-coding RNA (EBER) is present in almost all cases. Although genetic changes of LEL-CCA are unknown, the ability of EBV to induce epigenetic changes resulting in cell proliferation and oncogenesis is well recognized. Accordingly, LEL-CCA is characterized by DNA hypermethylation, in particular of cellular retinol-binding protein-I (CRBP1) and of cellular retinol-binding protein-IV (CRBPIV), significantly more frequent than in classical iCCA. The type of EBV latency in LEL-CCA has been elucidated only in part. EBERs were positive in almost all cases, latency membrane proteins-1 and -2 (LMP1 and LMP2) were negative in eight tested samples, and LMP-related gene showed a 30 bp deletion in two tested cases. Thus, similar to nasopharyngeal carcinoma, the expression of EBV-related antigens and tumour genetics might drive the lymphocyte recruitment. Expression of PD-L1 has been studied in LEL-Ca and compared with iCCA, showing a much higher rate in LEL-CCA in both tumour and tumour-infiltrating cells, though the latter were not specifically phenotyped. In theory, these findings challenge the hypothesis that PD-L1 is associated with a poor prognosis. However, in lymphoepithelioma-like hepatocellular carcinoma (LEL-HCC), where strong PD-L1 expression was similarly reported, the infiltrating cells mostly consist of T cells, and the ratio of CD8+ to FoxP3+ Treg cells is high, suggesting that in this setting, a favourable long-term outcome is not at odds with an up-regulation of PD-L1. It remains to be evaluated whether the same holds true in LEL-CCA.

8 | MODULATING EACH SINGLE CELL COMPARTMENT FOR THERAPEUTIC GAIN IN ICCA

In the last years, technological advances such as next-generation sequencing (NGS) have unravelled the high genomic and transcriptomic heterogeneity of iCCA, uncovering promising molecular targets for therapeutic intervention. While therapy targeting the cancer cells becomes increasingly more individualized, the contribution of the tumour microenvironment especially in highly desmoplastic tumours appears now clearer. The number of molecular biomarkers derived from each cell compartment of the tumour microenvironment holding prognostic value in CCA is summarized in Table 1. Furthermore, given the uniform reactive phenotype, the tumour stroma is additionally, an attractive therapeutic target. In this regard, promising strategies include molecular targeting of tumour cells, CAFs, immune cells and vascular cells (Table 2). Among tumour cell targeted therapy, we will discuss only those related to fibroblast growth factor receptor (FGFR) mutations as recently turned-out to be potentially relevant also for the modulation of the microenvironment. A comprehensive review of the novel mutation-based tumour cell targeted strategies is outlined in the specific chapter of the present special issue, which the reader may eventually refer to.

8.1 | Tumour cell targeted therapy

Within the last decade, the knowledge of molecular subtypes of CCA expanded remarkably. Identification of druggable targets and candidate molecules is gaining traction based on NGS. Exploiting FGFR mutations in CCA is one of the most advanced, promising approaches, together with therapies directed against EGFR, especially Her-2 mutations and IDH directed treatments. Whole-exome sequencing of predominantly liver fluke-negative, hepatitis virus-negative ICCAs by the Cancer Genome Atlas (TCGA) identified inactivating mutations in tumour suppressor genes, including ARID1A, ARID1B, BAP1, TP53 and PTEN as well as gain-of-function mutations in the oncogenes IDH1, IDH2, BRAF and KRAS. Interestingly, focal losses of CDKN2A, encoding p16INK4A, which inhibits the cyclin-dependent kinases CDK4 and CDK6 were observed and at a substantially higher proportion (up to 15%) than reported previously.

8.1.1 | Receptor tyrosine kinase inhibitors (TKIs)

Advanced stage solid malignancies, including iCCA are included into several selective and non-selective FGFR inhibitors for early phase clinical trials. Pan-FGFR inhibitors as NVP-BGJ398 and erdafitinib showed potential as well manageable safety profiles. NVP-BGJ398 showed impressive results by a disease control rate of 82% and tumour-activity results of erdafitinib from the ongoing phase II trial (NCT02699606) will be presented soon. Panatinitib, another non-selective TKIs showed promising efficacy for FGFR2 fusions in patients with iCCA and is currently evaluated in an ongoing phase II trial (NCT02265341). Several early phase I and phase II studies with selective FGFR-inhibitors including iCCA are ongoing like derazantinib (NCT01752920), TAS-120 (NCT02052778), Debio 1347 (NCT01948297) and INCB054828 (NCT02924376, NCT02393248).

Recently, an elegant experimental study shows that FGFR inhibition causes cell necrosis in human CCA cells, down-regulating the expression of the myeloid cell leukemia 1 (Mcl1), a member of the Bcl-2 family of anti-apoptotic proteins. Necrosis is caused by the cellular depletion of Mcl1 within the mitochondrial matrix which impairs mitochondrial functions. Notably, cell death by necrosis induced by FGFR inhibition may be synergic for either chemotherapy, dampening intrinsic anti-apoptotic cellular resistance of CCA, or immunotherapy, by eliciting a strong immunological anti-tumour response.

8.2 | Manipulation of CAFs

CAFs isolated from CCA patients show an enhanced susceptibility to apoptosis which results from an imbalance of Bcl-2 family members. Of note, the pro-apoptotic drug navitoclax, an inhibitor of Bcl-2, Bcl-xL and Bcl-w, selectively induces apoptosis in CAFs and reduces tumour growth, as well as peritoneal and lymph node metastasis in a syngeneic rat model of CCA.
Moreover, A-1331852, a specific inhibitor for Bcl-xL, is able to induce apoptosis in activated fibroblasts and reduces biliary fibrosis in a mouse model of primary sclerosing cholangitis, a pre-malignant condition of CCA. Thus, these data strongly support selective deletion of CAFs with Bcl-2 inhibitors as a therapeutic strategy in CCA.
checkpoint molecules are upregulated in 45% of BTCs. One of the latest development approaches in this field. So far, there are CTLA-4 and PD-1/PD-L1 inhibitor are established for cancer immunotherapy. Studies of molecular phenotyping showed that immune response. Chimeric antigen receptor (CAR) T-cell therapy is aimed to enhance tumour cell recognition and anti-tumour immunity is a promising new approach in cancer therapy. As previously mentioned, two molecules are of special interest in this regard. CTLA-4 and PD-1/PD-L1 inhibitor are established for cancer immunotherapy. Studies of molecular phenotyping showed that immune checkpoint molecules are up-regulated in 45% of BTCs. Further studies found overexpression of PD-1/PD-L1 in iCCA. Interestingly, tumours with immune checkpoint dysregulation showed less differentiated histology and more advanced tumour stage with worse outcome. However, data on immunotherapy in CCA are still scarce. The anti-PD-1 antibody pembrolizumab is under investigation in a phase II trial (NCT02628067). Preliminary data show promising efficacy in CCA with about 40% response rate. The PD-L1 inhibitor nivolumab has just been approved for HCC while data for CCA are still missing.

Besides immune checkpoint inhibitors, adoptive cell immunotherapy is a novel approach. Genetic reprogramming of autologous immune cells aims to enhance tumour recognition and anti-tumour immune response. Chimeric antigen receptor (CAR) T-cell therapy is one of the latest development approaches in this field. So far, there are no adoptive immune cell therapies under clinical investigation for CCA.

### 8.3 Immunotherapy

Self-tolerance and protection of normal tissue during immune responses is maintained by immune checkpoints. These immune checkpoints are frequently altered by cancer cells to escape immune surveillance. Restoring the immune response to evoke anti-tumour immunity is a promising new approach in cancer therapy. As previously mentioned, two molecules are of special interest in this regard. CTLA-4 and PD-1/PD-L1 inhibitor are established for cancer immunotherapy. Studies of molecular phenotyping showed that immune checkpoint molecules are up-regulated in 45% of BTCs. Further studies found overexpression of PD-1/PD-L1 in iCCA. Interestingly, tumours with immune checkpoint dysregulation showed less differentiated histology and more advanced tumour stage with worse outcome. However, data on immunotherapy in CCA are still scarce. The anti-PD-1 antibody pembrolizumab is under investigation in a phase II trial (NCT02628067). Preliminary data show promising efficacy in CCA with about 40% response rate. The PD-L1 inhibitor nivolumab has just been approved for HCC while data for CCA are still missing.

Besides immune checkpoint inhibitors, adoptive cell immunotherapy is a novel approach. Genetic reprogramming of autologous immune cells aims to enhance tumour recognition and anti-tumour immune response. Chimeric antigen receptor (CAR) T-cell therapy is one of the latest development approaches in this field. So far, there are no adoptive immune cell therapies under clinical investigation for CCA.

### 8.4 Angiogenesis inhibitors

Although pro-angiogenic factors such as VEGF, are expressed in 50% of iCCA, the clinical relevance of angiogenesis inhibitors in iCCA remains controversial. A clinical phase II trial using bevacizumab, a humanized antibody targeting VEGF-A, in combination with gemcitabine and oxaliplatin (GEMOX), demonstrated a partial response in 41% of patients. Sorafenib, a tyrosine kinase inhibitor acting on VEGF receptors (VEGFR) and PDGFRs, reduced tumour growth in iCCA mouse models but failed in clinical trials as single agent therapy or in combination with chemotherapy. To further explain the disappointment with angiogenesis inhibitors, it must be underlined that quite surprisingly, the main route of CCA dissemination through the lymphatic vascular system has not been considered yet for selective targeting. Interestingly, in a xenograft model of iCCA, targeting VEGFR-3 receptor (cognate of the main lymphangiogenic growth factor VEGF-C) markedly reduced tumour-associated lymphangiogenesis. Further investigations should also focus on the identification of CCA subgroups (eg patients with enhanced PDGF-BB level) who might benefit from angiogenesis inhibitors.

### 9 Conclusions

Studies in animal models and human samples have expanded the concept of the tumour microenvironment as a functional component central to tumourigenesis and tumour progression especially in epithelial cancers featuring an exuberant desmoplastic reaction. Within the multiple cell elements populating the microenvironment, new actors in particular from the immune system, have been added to the formerly characterized CAFs and TAMs, and make the interplay among them and with the tumour cells extremely intricate. Consequently, recent observations have argued against the original view that combinatorial interactions between different factors released in the tumour microenvironment boost the pervasive phenotype of cancer cells. Here, we have dissected the pleomorphic functions of stromal and immune reactions in CCA (summarized in Figure 2). In this regard, LEL-CCA is paradigmatic of the protective role played by the immune milieu and this model will deserve strong attention by future studies aimed at testing efficacy of immunotherapy. On the other hand, very recent studies have further validated the pro-invasive functions exerted by
stromal cells, showing that besides directly supporting the proliferative and invasive potential of cancer cells, CAFs provide them with a rich lymphatic vasculature instrumental for their early dissemination. Indeed, CAF depletion has led to significant anti-tumour effects in CCA. However, the considerable heterogeneity of CCA requires a multimodal, multiagent therapy that besides including tumour-promoting stromal cells, will gain traction from high throughput screening of target molecules and NGS-based stratification of patients, to identify and explore new effective and more personalized therapeutic approaches.157
